# Lecture 11: Hashing

(CLRS 11.1-11.3)

June 3rd, 2002

### 1 Maintaining ordered set

- Last time we started discussing the problem of maintaining an ordered set S under operations
  - Search
  - Insert
  - Delete
  - Successor
  - Predecessor
- We discussed several implementations
  - Array
  - Linked list
  - Skip lists
- We saw that in skip list all operations have *expected* running time  $O(\log n)$ 
  - Next time we will discuss a data structure (red-black tree) with worst-case  $O(\log n)$  running time.
- We can argue that Θ(log n) time is optimal for searching in the decision tree model Recall decision tree model:
  - Binary tree where each node is labeled  $a_i \leq a_j$
  - Execution corresponds to root-leaf path
  - Leaf contains result of computation
  - Decision trees correspond to algorithms where we are only allowed to use comparison to gain knowledge about input.
  - Decision tree for SEARCH must have n leaves (one for each element)  $\downarrow$ 
    - Tree must have height  $\Omega(\log n)$
- In the case of sorting, we saw that we could be at the  $\Omega(n\log n)$  decision tree lower bound using Indirect Addressing (Radix sort)
  - we can also use indirect addressing idea on ordered set problem.

#### 2 Direct Addressing

• Store element e in cell e of array (we assume elements are integers)

- INSERT/DELETE/SEARCH in O(1) time
- PREDECESSOR/SUCCESSOR in O(|U|) time (|U| is the size of "universe" U)
- Note: We could make PREDECESSOR/SUCCESSOR efficient by linking neighbor elements, but then Insert/Delete becomes O(|U|)
- Problem is that |U| can be huge and often |U| >> n

- 32 bit integers  $\Rightarrow |U| = 2^{32}$ 

• We can reduce space use using "hashing"

### 3 Hashing

• To introduce hashing, we look at direct addressing in a slightly different way :

- The main idea is to fix the table size to m = O(n))
  - now element *e* cannot be stored in cell *e*  $\Downarrow$

We introduce hash function  $h(e): U \to \{0, 1, \dots, m-1\}$ 

We call the array the *hash table* 

- Problem is of course that several elements can be stored in same cell (m < |U|)
  - We call such an event a *collision*
- We solve this problem using *chaining* 
  - Elements mapping to same cell are stored in linked list

- INSERT/DELETE/SEARCH in  $O(\max \text{ chain length})$
- PREDECESSOR/SUCCESSOR in O(m+n) since we have to look in all cells and chains

(Note : We assume we can compute h(e) in O(1) time)

- Note: PREDECESSOR/SUCCESSOR bounds are very bad (we will not discuss them further in the following)
  - We call a data structure only supporting INSERT/DELETE/SEARCH a Dictionary
  - In a dictionary, order does not really matter
  - Lots of applications of dictionaries, e.g.
    - \* Symbol table in compilers
    - \* IP addresses to machine-name table
- Performance of hashing depends on how well h(e) spreads the elements in the hash table
  - Lets make the simple uniform hashing assumption

Any given element is equally likely to hash into any of the m cells

∜

- On average  $\frac{n}{m}$  elements in each chain
- If we choose m = O(n) we get O(1) bounds (and O(n) space)
- How do we choose a good hashing function?
  - Often  $h(e) = e \mod m$  is used  $(e \mod m$  is remainder of e divided by m) Example :  $m = 12, e = 100 \Rightarrow h(e) = 4$  since  $100 = 8 \cdot 12 + 4$
  - -m is often chosen to be a prime number far away from a power of 2

If  $m = 2^p$  then h(e) = lowest p bits in e which means that the hashing value only depends on some of the bits in e. If data is not random—not all p-bit patterns equally likely—then this might be a very bad choice, we would rather have h(e) depend on all the bits

### 4 Universal Hashing

- Given hash function h, we can always find sets of elements that make hashing perform badly (n elements that map to same location)
- Like in Quick-sort and skip lists we can make sure our data structure does not perform badly on a particular input (set of inputs) using randomization
  - We choose a hash function randomly (independent of elements) from a carefully defined set of functions
    - ∜
  - no worst case inputs
  - good average case behavior
- We want the set of hash functions to be *universal*

Let *H* be a finite collection of functions  $U \to 0, 1, ..., m - 1$ . *H* is called **universal** *if and only if* for each  $x, y \in U$  the number of functions  $h \in H$  for which h(x) = h(y) is precisely |H|/m.

- If we choose h randomly from H then the probability of collision between x and y is  $\frac{|H|/m}{|H|} = \frac{1}{m}$
- If m > n, then then expected number of collisions involving element e is < 1  $\downarrow$ 
  - INSERT/DELETE/SEARCH in O(1) expected
- Note: The book proves the above more formally and talks about how to find universal class of hash functions (not hard but requires some number theory, so we skip it)

# 5 Dynamic perfect hashing

- It turns out that one can even do searches in O(1) worst-case time
  - Out of scope of this class
- Idea:
  - If set of n keys is static, we could potentially find a *perfect* hash function h

- We need to be able to store description of h compactly and compute h fast.

- Lots of research has been done on finding perfect hash functions for a given set of elements, resulting in O(1) worst-case SEARCH
- The perfect hashing idea can even be made dynamic such that one also gets O(1) IN-SERT/DELETE expected running time.
- Lots of recent results even improve on this.
